Abstract

Using a Regression Discontinuity Design (RDD) and publicly available datasets, this study measures the effect of the Iranian Cultural Revolution, during which all institutions of tertiary education were closed for 30 months, on college attainment rates of affected cohorts. The results show that this elimination of higher education supply reduced men's college attainment rate by only two percentage points (about 15%) while it had no impact on women's. Moreover, using this natural experiment, it finds the returns to college and above education to be about 100%. These results provide an example showing that when demand for education is high, a temporary reduction in supply may have little long-term impact.

1. Introduction

"History is everything. Everything is history." This was the title of an event I attended at Harvard University a few years ago, in which some of the best Harvard historians gave intriguing lectures on how important history has been in shaping humanity today and tomorrow. Path-dependent equilibria have been long discussed in economics as well. Maybe one of the most important forces in history are revolutions, which upset political, social, and economic equilibria and shape destiny of generations. The Islamic Revolution of 1979 in Iran is one that arguably changed the path of not only Iran, but also the rest of the Middle East.

This study documents the effect of one of the largest disruptions in tertiary education in the world that occurred after this revolution. In this disruption, which was named the *Cultural Revolution* (reminding of its Chinese predecessor), the post-revolutionary government shut down all institutions of higher education, until further notice, in order to clear the universities from all anti-regime political activities, particularly by the leftist student groups. About half of the university professors, who were considered leftist (Ashraf 1997), and numerous students were expelled across the country. Universities remained closed for 30 months, inhibiting three cohorts of high school graduates from entering college. Moreover, three months after the closure of universities, Saddam Hussein attacked Iran, after which these cohorts were all drafted into the longest war of the 20th Century. As a result, some call these cohorts the "burnt generation." This paper evaluates the accumulated effect of these events on the college attainment of affected cohorts about three decades after the events. Using a Regression Discontinuity Design and publicly available datasets[1], it finds that these events reduced men's attainment rate of college and above education by only about 2 percentage points (i.e., about

---

[1] The datasets are 2006 and 2011 censuses available on IPUMS International website. I intentionally avoid using earlier censuses (the 1986 and the 1996 censuses) as I want all the results to be replicable. The earlier censuses are not publicly available.

15%). Women, who were only affected by the Cultural Revolution (not the draft), did not experience any impact on their college attainment rate.

This relatively small effect is surprising for several reasons. The affected cohorts had to take a difficult national examination, with about 20-30% chance of success, to enter college. Their competitors in this exam were fresh out of high school and well-versed in the topics of the exam while the affected cohorts had been away from school for several years. In addition, serving in the Iran-Iraq war left physical and mental scars on the affected cohorts, from post-traumatic stress disorder (PTSD) to losing limbs, which could have negatively affected their interest in taking the exam and their performance in it. On the supply side, universities capacity after the Cultural Revolution was lower as half the faculty were purged. But one factor that benefited the affected cohorts was that it was easier for war veterans to pass the college entrance examination as they received quotas on seats. But, overall, it is interesting that the long-run effect on affected cohorts is smaller than once expects.

I use the exogenous effect of these events on men's education to estimate returns to tertiary education free of bias. Although OLS estimates show that individuals with college level education and above have 76% higher hourly wages than those with less than a college education, the IV estimates show a 100% return on hourly wages as a result of earning college or greater level of education.[2] In other words, on average, if people with less than college education receive tertiary education (randomly), their hourly wages would double. Including only those with at least high school diploma in the sample, does not create a statistically different estimate. This large return may be the reason for the small long-run effect of the aforementioned historical events. The large return

---

[2] In his dissertation, Souri (2004) has used deviations from the trend in college attainment rate for cohorts affected by the Cultural Revolution as an instrument for college attainment to estimate returns to education. This study, however, uses an RDD in the first stage of the IV estimates. It argues that the first stage satisfies the exclusion restriction better than a deviation from the trend instrument.

motivated a large demand for education in these cohorts and enticed them to continue their education after colleges re-opened and they returned from war.

These results offer an example that a temporary reduction of supply of education may not have long-term consequences, probably when demand for education is high. The paper is also about the most under-studied countries, Iran. Moreover, the results also contribute to the scarce literature on returns to tertiary education. Two of the notable studies in this area are Maurin and McNally (2008) and Ozturk and Tumen (2018) who use the impact of students protests on college attainment in France and Turkey respectively to estimate returns to tertiary education.

There are almost no studies that estimate returns to education free of bias in the Middle East and North Africa (MENA) region (except for Turkey), despite the fact that these returns are the subject of heated discussions in policy and academic circles. The MENA region is the only region in the world where unemployment is higher for college educated than for less-than-college educated. Hence, some argue that returns to college education are low and some college graduates are over-educated. This study is the first to contribute to this discussion by estimating the returns in a MENA country free of bias. It finds that contrary to public perception, return to college education is substantially high. Moreover, although unemployment for college-educated youth might be higher, it does not find any evidence for that in this quasi-experimental setting for Cultural Revolution cohorts who are older.

The rest of this paper is organized as follows: Section 2 explains the Cultural Revolution in Iran. Section 3 is about the data, and Sections 4.1 through 4.3 present and discuss the evidence. Section 4.4 reports the estimates on returns to education. The paper concludes in Section 5.

2. Cultural Revolution in Iran

The Islamic Revolution of 1979 in Iran has been a turning point in the recent history of the country. From the onset, its leaders viewed this political revolution as a cultural and ideological revolution that aimed to establish a new paradigm in Iran to replace notions of Western culture (Mehran 1997). Reforming cultural institutions, particularly the educational system, was identified early on as a high priority. Universities were of special importance, as they were key centers of political activity during and after the revolution.

In the initial months after the revolution, the transitional cabinet of Prime Minister Bazargan, composed of moderate religious nationalists, protected most political freedoms. But within days of the occupation of the U.S. Embassy in Tehran by Islamist and leftist groups on November 4, 1979, the transitional cabinet resigned en masse. Leftist groups, whose stronghold was the universities, vied with Islamist groups to fill the resulting power vacuum. Therefore, the political elite, mostly consisting of Islamist groups, viewed the political activities on university campuses as a major source of instability. In an April 18, 1980, speech, Ayatollah Khomeini voiced concerns about the universities, stating, "We are not afraid of economic sanctions or military intervention. What we are afraid of is Western universities and the training of our youth in the interests of West or East."[3] Soon after, violent fights broke out between Islamist and leftist groups in the universities, providing the government with an excuse to order shutdown of all institutions of higher education on June 12, 1980, until further notice.[4] Thus began one of the most important educational projects in the recent history of Iran: the overhaul of the higher education system, a.k.a. the Iranian *Cultural Revolution*.

---

[3] Bakhash (1984), page 201.
[4] For a detailed account of events, see Bakhash (1984) and Hiro (1985).

The Cultural Revolution Committee was established on June 13 by the government to manage the process, with goals to purge universities of leftist faculty and students, add new courses on ideologies of the revolution and religion to every discipline, and train new faculty to replace those purged. Closure of universities gave the committee an opportunity to implement their goals. As part of this process, roughly 8,000 faculty members with leftist dispositions or approximately half the total number of professors in the country were purged from the universities (Ashraf 1997). Most either left the country or transitioned to private businesses. Leftist students were also expelled and barred from re-entering college until almost a decade later.

On September 22, 1980, less than four months after closure of the universities, Saddam Hussain attacked Iran and sparked the longest war of the 20th century.[5] All high school students who reached age 18 in 1980 and the subsequent two years were forcibly conscripted into the military, and were thus drafted into war. During 1982, the universities gradually re-opened, first by allowing students needing 25 or fewer credits to graduate to enroll in the spring of 1982. On December 18, 1982, after 30 months of closure, the universities re-opened to prior students requiring more than 25 credits to graduate, and the first new cohort enrolled in the fall of 1983.

The group of high school students fully affected by the closure of universities comprises three cohorts, namely those who graduated high school and could have enrolled in university in 1980, 1981, or 1982. No question in the data specifically asks whether an individual belongs to this group. In other words, no question asks whether an individual could potentially enter college in 1980, 1981, or 1982. But one can argue that at least for men, this group consisted of individuals who were 18 in 1980, 1981, or 1982. This is because male high school graduates could try to enter college before age

---

[5] Abrahamanian (2008) compares this war to World War I in terms of military tactics such as trench warfare, human wave attacks of the Iranians, and the use of chemical weapons such as mustard gas by the Iraqi government. The human wave attacks, in particular, required a large body of soldiers and maximized demand for recruits.

18. After reaching 18, they were required to do military service. Mandatory military service was particularly well enforced at the time,[6] as the country was at war with Iraq and soldiers were in high demand. Even after completing two-year mandatory service, men could not immediately try to enter college due to new age limits on college entrants, imposed by the government in the initial years following the Cultural Revolution.

Women were not subject to mandatory military service and could have attempted to go to college even after they reached 18. Women who turned 18 in 1980, 1981, or 1982, and wanted to go to college but were unable due to university closures, had two remaining options: wait to apply to college until an unknown future time when universities would presumably re-open, or get married. These two options are largely mutually exclusive in Iran, as the chance to pursue higher education was negligible after marriage and starting a family. Given that the median age at first marriage for women was approximately 17 years of age at the time,[7] women affected by the Cultural Revolution experienced significant pressure to marry, particularly in light of the uncertainty surrounding if and when universities would re-open. In this paper, we estimate the effect of university closure on educational attainment of both male and female cohorts who turned 18 between 1980 and 1982. The effect on women presumably only shows the effect of the Cultural Revolution.

Cohorts who turned 18 in 1977, 1978, and 1979 and were already enrolled in college when the Cultural Revolution occurred experienced interruption of their education until the universities re-opened. These cohorts were potentially less likely to finish their education or attain higher levels of education (e.g., graduate school). As partial and full completion are coded similarly, we cannot

---

[6] It is still very well enforced.

[7] Median age at first marriage for women who were 10 to 29 years old in 1980 was 17, according to the Demographic and Health Survey of 2000.

identify partial vs. full completion of college in this data; it is not possible to estimate the effect of the Cultural Revolution on college completion of these cohorts.

3. Data

Two sets of data are used in this study. The first set contains the combined 2% censuses of 2006 and 2011 in order to estimate the impact of the Cultural Revolution on educational attainment. As the censuses do not contain hourly wages, a second set of data, the Annual Household Income and Expenditure Surveys (HIES) from 2006 through 2015, is used to estimate the return to education, using the Cultural Revolution as an instrumental variable for education. The Statistical Center of Iran (SCI) collects these datasets; both censuses are available on the IPUMS International website, and the HIES datasets are available on the SCI website.[8]

The 2% nationally representative samples of censuses have over 2.78 million individuals and over 750,000 households combined. At the individual level, the data contain demographic information such as gender, age, relation to the head of household, birth year and month, education, employment and job characteristics, marital status, number of children ever born, migratory status, reasons for migration, and more.

The largest sample used in this study consists of individuals born between 1931 and 1984. Summary statistics of all variables for this sample are reported in Table 1, Panel A. As shown in Panel A, 77% of this sample is literate and about 13% have attended college. The number of observations with recorded birth month is about 3% smaller than the sample with recorded birth year (1,372,865 vs. 1,419,591); the results are separately analyzed based on birth month and birth year.

---

[8] The IPUMS website address is https://www.ipums.org/ and the SCI website address is http://amar.org.ir/english (accessed on Jan. 5, 2018). Note that these URLs could change.

HIES has been collected annually since 1984, and contains disaggregated expenditure and income as well as some household demographic data. Since 2006, hours worked have been collected as part of this survey. (HIES is one of the few datasets in Iran that collects hours worked.) These data allow us to calculate wages and estimate the return to education. Each survey since 2006 has about 31,000 to 39,000 households. Rural areas are over-sampled. The surveys are generally used to estimate macro-level variables such as inflation, and thus have detailed disaggregated expenditure data. After censuses, HIES is the most important and regular project of the Statistical Center of Iran, but contains limited demographic data. For example, although the censuses have year and month of birth, HIES data includes only age, allowing only birth year (not birth month) to be constructed. Summary statistics of the variables used from the HIES survey are reported in Table 1, Panel B.

An important issue with all Iranian surveys (censuses and HIES) is that education is only identifiable by level: primary, middle school, high school, college, and graduate school. Years of education, grades, and whether the educational level was partially or fully completed are not included. Therefore, our outcome variable can best be defined as a dummy variable that shows whether the individual has partially or fully completed college or graduate school. This dummy variable is termed "College and above" throughout the rest of this paper.

One technical point is that birth years and months in the non-harmonized IPUMS data are recorded based on the Persian calendar: although the Persian calendar is a solar calendar, it does not match the Gregorian calendar. The Persian calendar, which has been in use in Iran, Afghanistan, and Tajikistan for centuries, runs from spring equinox (the first day of spring, typically March 20) to the day prior to the next spring equinox. Thus, each year of the Persian calendar overlaps with the last nine months of each year of the Gregorian calendar and the first three months of the following year

of the Gregorian calendar.[9] For simplicity, in this paper, each year on the Persian calendar is approximated as the Gregorian year with which it has the longest overlap (i.e., nine months). For instance, the Persian year 1390 (which ran from March 20, 2011, to March 19, 2012) is approximated as the year 2011 on the Gregorian calendar.[10] This approximation is used only to simplify presentation of the results in graphs but is not used in the econometric analysis.

4. Methodology and Results

As discussed in Section 2, it is not possible definitively to identify subjects within the datasets who were eligible to apply for college but unable to do so during the Cultural Revolution, due to the closure of universities. Because of mandatory military service, however, age (or birth year) at the time of the Cultural Revolution can be used to identify the cohort of men who would have entered college but were unable to do so due to the closure of universities. These are the cohorts who turned 18 in 1980, 1981, or 1982, born between 1962 and 1964. They were fully affected by the Cultural Revolution, while those already attending university at the start of the Cultural Revolution in 1980 were partially affected, as their education was interrupted by the Cultural Revolution. These cohorts who turned 18 in 1977, 1978, or 1979, were born between 1959 and 1961.

---

[9] Each month in the Persian calendar matches a zodiac sign. The Persian calendar was devised by mathematicians and astrologers in the 11th century upon request from the king, Jalal-e-Din Malek Shah. As a result, it is also called the Jalali calendar. Although widely in use since then, on February 21, 1911, the Iranian parliament adopted it as the official calendar. On March 31, 1925, the parliament made small modifications in the number of days in each month to simplify the calendar. Based on that, the first six months have 31 days and the next five months have 30 days. The last month has 29 days, or 30 days in leap years. The time a year ends and a new year begins is not at midnight (like the Gregorian calendar). Instead, it is the exact time on March 20 or a close date when the spring equinox occurs. (This time is when the distance between the earth and the sun is at its average. This specific time can be precisely calculated. For instance, the year 1395 started at 8:04:30 p.m. on March 20, 2016 (Tehran time).

[10] This is in fact what one finds in the harmonized IPUMS birth year and month variables. They are based on the Gregorian calendar. Unfortunately there is a mistake in the IPUMS data: January and February of each year are incorrectly attributed to the prior year. For example, although the last three months of 1390 belong to 2012, in the data they belong to 2011 because 1390 is solely associated with 2011.

Figures 1(a) and (b) describe college attainment rates across cohorts for men and women, respectively. Birth year is shown on the horizontal axis, while the share of the population with college level education or above (undergraduate or graduate level education) is shown on the vertical axis. There are only 54 birth year cohorts with sufficient observations who were old enough in 2006 or 2011 to have attended college, namely the birth cohorts between 1931 and 1984. Each data point represents the share of any given birth cohort who had fully or partially completed college education or above. As discussed in the data section, we cannot distinguish full and partial completion. These cohorts are between 22 and 80 years of age in the censuses collected in 2006 and 2011. Cohorts fully or partially affected by the Cultural Revolution are marked with dark gray or light gray bars, respectively.

As depicted in Figures 1(a) and 1(b), there is an upward trend in college attainment rates as one moves from older to younger cohorts. This trend has been documented in the past in Salehi-Isfahani (2005) and Majbouri (2010), among others. Examination of Figure 1(a) reveals that the share of men with college education or above in cohorts fully affected by the Cultural Revolution (1962, 1963, and 1964 cohorts) deviates downward from this general trend. The rate is approximately between one to two percentage points lower than what it could have been if the pre-Cultural Revolution trend continued uninterrupted for these male cohorts (14% vs. 15.5%).

Interestingly, for women, the trend in college attainment rate is continuously upward and appears without discontinuity, even for cohorts affected by the Cultural Revolution (Figure 1(b)). The rise in female college attainment rate has been exponential and faster than for males; and by the late 2000s, two-thirds of students enrolled in college were women.[11]

---

[11] Aside from visual observation, one can estimate the deviation from the trend for the affected cohorts. In brief, one assumes various functional forms for the trend and estimates the deviations from those functions at the time of the

4.1 Regression Discontinuity Using Birth Years

As the Cultural Revolution results in university closures for three cohorts born just before 1964, with subsequent re-opening of universities to cohorts born after 1964, a discontinuity in attainment rates at the 1964 birth cohort is expected.

Figures 2(a)-(c) fit three different polynomials (first order, second order, and local smooth polynomial, respectively) to the cohort of men born before and after the 1964 birth cohort. Data for the same process in the sample of women born before and after the 1964 cohort is shown in Figures 2(d)-(f). The horizontal axes represent the birth year cohorts measured as the number of years after the threshold year 1964. The vertical axes indicate the share of each cohort who partially or fully completed undergraduate or graduate schools. For men, visual examination of the graph suggests a discontinuity at 1964; cohorts born immediately prior to 1964 have lower attainment rates than those just after 1964. For women, however, the results are inconclusive. The discontinuity for women is positive and small in a first-degree polynomial (Figure 2(d)), but negative and small in the others.

Figure 2 suggests an RDD in which the running variable is birth year.[12] The few discrete values of the running variable means that recently developed optimal bandwidth choice methods and local linear estimations may not be employed as they do not converge, but standard polynomial regressions should be used. To check for robustness, however, various bandwidths should be considered. Table 3 shows the result of the following standard RDD:

Cultural Revolution. These deviations do not show causal effects. Detailed explanation and the results of such analysis are reported in Online Appendix A.

[12] Figure OB1 in the Online Appendix B is a comparable set of figures that uses the full data, i.e., 54 birth year cohorts between 1931 and 1984.

$$C_i = \alpha + \beta D_i + \sum_{l=1}^{L} \gamma_l (B_i - 1964)^l + \sum_{l=1}^{L} \delta_l D_i (B_i - 1964)^l + u_i, \quad L = 1, 2 \quad (1)$$

in which C_i is a dummy equal to one if individual i has partially or fully attended undergraduate or graduate school.[13] B_i is the year individual i was born (i.e., birth cohort). $B_i - 1964$ is the running variable in the RDD.[14] L is the degree of the polynomial control for the running variable; Gelman and Imbens (2018) argue that employing higher than second order polynomials is not beneficial. Therefore, I restrict the current model to first and second order polynomials. D_i is a dummy variable, set equal to one if individual i was born in or before 1964, and zero otherwise. The coefficient of D_i (i.e., β) shows the local average treatment effect of the Cultural Revolution. Lee and Lemieux (2010) suggest that when the running variable is discrete, standard errors should be clustered at the discrete values of the running variable. Following this, all regressions in this model include cluster-robust heteroskedastic standard errors. Interestingly, in this study, if one does not cluster standard errors, or cluster them based on the 60 geographic regions of Iran, she gets smaller standard errors and hence, more statistically significant estimates of the effects.

The left and right sections of the top panel in Table 2 report the local average treatment effect, β, for men and women, respectively. Fifteen birth cohorts before and after the threshold (i.e., 1950 through 1979) were included in these regressions. All specifications for men, reported in Columns (1) and (2), show a negative and statistically significant effect of the Cultural Revolution and the successive draft on attainment rates.

---

[13] As mentioned before, the data do not distinguish between full and partial completion of college or graduate school.
[14] The year 1964 is the cutoff point based on the Gregorian calendar. As the birth year is reported in Persian calendar format in the data, however, 1964 is equivalent to 1343 in the data. Therefore, B_{is} is the Gregorian birth year subtracted by 1343. Following Cattaneo et al. (2017), the birth year 1343 is changed to 1342.999 to make sure it falls on the other side of the threshold.

Similar to Figures 2(d)-(f), the results for women shown in columns (3) and (4) depict little evidence of discontinuity. There is a statistically significant discontinuity only for the first order polynomial setting, which switches sign and becomes insignificant in the second order specification. Interestingly, as in Figure 2(d), the coefficient in the first order setting is positive, which implies the unexpected result that the Cultural Revolution increased female educational attainment. Figures 1(b) and 2(d)-(f), however, show that the trend in college educational attainment for women is not linear but quadratic, with the result that the correct specification is not the first-order polynomial, but the second-order. Hence, one can conclude that there was no effect of the Cultural Revolution on women's college attainment rates.

Since the number of mass points of the discrete running variable (i.e., the number of birth years) is small, optimal bandwidth choice methods cannot be implemented. Therefore, one needs to check the robustness of the RDD using various bandwidths. The bottom panel shows the local average treatment effect when we change the bandwidth from 15 years to 8, 10, 12, and 20 years before and after 1964. Each row represents a bandwidth size and each column is a polynomial order (first and second order). For men (the left section of the bottom panel), the results are always statistically significant (mostly at 1% level). They robustly show that men's college attainment rate decreased by about 0.8 to 2.2 percentage points (about 7% to 17%) due to the Cultural Revolution and the successive draft.

As the right section of the bottom panel shows, for women, there is no discontinuity in almost all specifications and bandwidth choices. In the two out of 10 instances for which the discontinuity is statistically significant, it takes a positive sign, implying that the Cultural Revolution strangely increased educational attainment. However, both of these positive coefficients belong to the first order polynomial specification and as mentioned above, are unreliable. Therefore, there is no

evidence that the Cultural Revolution affected women. These results will be discussed further in Section 4.3.

4.2 Regression Discontinuity Using Birth Months

In Iran, as in many other countries, children can enroll in primary schools at the age of six. More specifically, those who reach age six before the new educational year begins (September 23 of every year) can start school in the same year. But those who reach age six after the educational year starts must wait to enroll in the following year. For example, a child born in July 1964 would have turned six in July 1970 and would thus have enrolled in and started first grade in September 1970 for the 1970-1971 academic year. A child born in December 1964, however, would have turned six after September 1970 and thus would not have been able to enroll in and start first grade until September 1971. In this way, not only birth year but also birth month create a discontinuity in the year an individual starts first grade.

The educational year in Iran starts on the first day of *Mehr*,[15] the seventh month of the year, which corresponds to September 23 in the Gregorian calendar. Parents of children born in Mehr, and occasionally parents of children born in *Ābān*[16] (the eighth month), often feel it is unfair to have to wait an additional year for their child to start school, simply due to missing the cut-off by a few days. They often petition (usually successfully) to enroll their child in school in the year the child turns six. Thus, in practice, Ābān is a better cut-off point for the birth month the school year starts.

At the time of the Cultural Revolution, as now, every Iranian male is obligated to join military service in the month he turns 18 years old, with the exception of men who are enrolled in school. In

---

[15] Mehr is pronounced /ˈmehr/ (using Meriam-Webster pronunciation keys) and corresponds to Libra, the seventh zodiac sign. As mentioned in footnote 7, each month in the Persian calendar corresponds to an astrological sign.
[16] Ābān is pronounced as /ˈäbˈän/ (using Meriam-Webster pronunciation keys) and corresponds to Scorpio, the eighth zodiac sign. See footnote 7 for more information.

the case of a boy born a month before Ābān in 1964, he would be able to attend first grade in 1970, while a second boy born a month after Ābān of 1964 would not be able to attend first grade until 1971, a year later than the boy born before Ābān of 1964. Eleven years later in December 1982, the Cultural Revolution was about to end and universities were about to re-open the following year. The second boy would have been in the last year of high school, and thus able to enroll in university after universities re-opened, while the first boy would have finished high school and already been drafted into military service. The first boy would also have been less likely to enroll in college during his military service and for a period of several years after the end of the Cultural Revolution, as there was an upper age limit on who was eligible to enroll in university after the Cultural Revolution. As a result of these factors, there is an expected discontinuity in college educational attainment based on whether an individual was born before or after Ābān 1964.

Figures 3(a)-(c) and 3(d)-(f) illustrate this discontinuity for men and women, respectively. The running variable on the horizontal axes is the birth month, measured as the number of months since the threshold month of Ābān 1964 (months prior to Ābān 1964 are negative, and those following Ābān 1964 are positive). The vertical axes show the proportion of total population in each cohort with some degree of university-level education. Men born just before the threshold appear to be less likely to have any tertiary educational attainment. Based on the results for birth year (Table 2), one expects to see no discontinuity at the threshold for women, which is supported by Figures 3(d)-(f).

The running variable, month of birth since Ābān 1964, is a discrete variable. But as it can take over 600 values, we can employ optimal bandwidth selection procedures with local polynomial estimation. (For more information, see Calonico et al., 2017; Cattaneo et al., 2014a,b; and Cattaneo et al., 2017.) Table 3 reports the results for such estimations. There are two major methods of optimal bandwidth selection in the literature: 1) Coverage Error Rate (CER) and 2) Mean Square

Error (MSE). Each of these methods can find the same optimal bandwidths above and below the threshold (termed R.D.) or different optimal bandwidths above and below the threshold (termed Two-sided from now on). Thus, four different optimal bandwidths choice methods can be implemented: CER-Two-Sided, CER-R.D., MSE-Two-Sided, and MSE-R.D. For robustness, results are estimated for all four of these choices, as shown in Table 3. The data extends from the 1931 birth cohort to that of 1984. The year 1984 was chosen to ensure the youngest age in the sample is roughly 22 years of age (the 1984 cohort is about 22 years old in the 2006 census). The year 1931 is chosen as the number of observations drop quickly for birth year cohorts below 1931 (the 1931 cohort is 75 years old in the 2006 census and 80 years old in the 2011 census). For the data range selected, there are 245 birth month cohorts above (after) the threshold and over 400 below (before) it. Since the data is not symmetric around the threshold, different optimal bandwidth sizes should be chosen on the two sides of the threshold. Therefore, two-sided approaches (CER–Two Sided and MSE–Two Sided) are more relevant.

Table 3 depicts the results based on each of these optimal bandwidth methods with bias correction procedures.[17] The top panel reports the discontinuity in educational attainment, conditional on a first and second order local polynomial of the running variable when the optimal bandwidth choice method is CER-Two Sided. Interestingly, the estimates are close to those reported in Table 2 using birth year as the running variable. For men, there is a discontinuity of about 1.8 to 2.2 percentage points in college attainment rates. Both estimates of discontinuity for women in Columns (3) and (4) are statistically insignificant and close to zero.

The bottom panel reports the discontinuity using other optimal choice methods: CER-R.D., MSE-Two-Sided, and MSE-R.D. Each row reports one of these methods and each column presents an

---

[17] Robust and Conventional Estimates are almost identical to these results. They are reported in the Online Appendix, Tables OB3 and OB4.

order of the polynomial. Interestingly, all results for men are similar and statistically significant, regardless of the order of the local polynomial used or the optimal choice method implemented. The discontinuity ranges only from 1.0 to 2.2 percentage points (the same as birth year results.) Coefficients for women are similar to those found in the top panel as well, i.e., they are small and statistically insignificant.[18]

4.3 Discussion

During the Cultural Revolution in Iran, all universities were closed for 30 months. Three cohorts of young men faced immediate draft into the longest war of the 20th century, which resembled World War I in terms of military tactics, and massive casualties.[19] Yet unexpectedly, these cohorts exhibit only a slightly smaller college attainment rate than subsequent cohorts.

One potential explanation is that the affected cohorts disproportionately died during the war, reducing the overall population of those cohorts. As a result, fewer of the survivors would have to attend college to achieve the same overall educational attainment rates as cohorts not affected by the Cultural Revolution and war. If this is true, we should see a discontinuity in the size of cohorts at the threshold. Figures A1-A3 in the appendix plot the number of observations in each birth year and birth month cohort and fit multiple polynomial functional forms to the data. The figures present little evidence of discontinuity in the size of cohorts at the threshold. If anything, the cohorts

---

[18] As an alternative to using the individual level data, one can employ the average of college and above dummy for each birth month cohort (i.e., the share of individuals with college and above education in each birth month cohort) as the dependent variable in the RDD. The number of observations is reduced to the number of birth month cohorts, i.e., 648. The estimates, reported in Tables OB5-OB7 in the Online Appendix, are very similar to those reported using the individual level data in Table 3, but they only range between 1.4 and 2.2.

[19] Some scholars compare this war to World War I because of Iranian human wave attacks, bayonet charges, large-scale trenches with barbed wire along the front lines, extensive use of chemical weapons by Iraq, and deliberate attacks on civilian targets (Abrahamian 2008). Iranian use of human wave attacks and Iraq's extensive use of chemical weapons resulted in casualty rates on the Iranian side comparable to casualty rates in World War I.

affected by the Cultural Revolution (cohorts just below the threshold) seem to have more observations in the dataset than those who came afterwards.

Table A1 reports the results of estimating Equation (1) when the dependent variable is the number of observations in the birth year cohorts. This table is in the same format as Table 2. For women, understandably, the discontinuity in cohort size is almost always statistically insignificant and switches signs depending on the specification. The results for men also show that there is either no statistically significant discontinuity in cohort size, or when there is, the cohorts affected by the Cultural Revolution are larger in size.[20] Overall, there is no evidence of a smaller cohort size for the affected cohorts. Therefore, the reason behind the relatively higher-than-expected attendance rates for the affected cohorts is not that they were less likely to survive the war. If anything, they were more likely to survive. (Note that the next cohorts for whom universities opened were also drafted if they could not enter college.) According to the best estimates, the total number of casualties during this war (on the Iranian side) ranges from about 200,000 to 600,000 (Hiro, 1991; Abrahamian, 2008; Bercovitch and Jackson, 1997; Clodfelter, 1991; Palmowski, 1997; Mikaberidze, 2011); and these casualties were spread across many birth cohorts involved in the war. In fact, war casualties increased in later years. Hence, the size of post-Cultural Revolution cohorts drafted later could have been affected even more by the war. Therefore, war casualties should have had little impact on size of the affected cohorts relative to other cohorts.

One may argue that the small effect of the Cultural Revolution on educational attainment is due to competition between cohorts affected by the Cultural Revolution and post-Cultural Revolution cohorts for a limited number of university spots, and that this reduced the chances of those in the

---

[20] One can use the birth month cohorts and implement an RDD on cohort size using various optimal bandwidth choice methods. Results of this approach are shown in Table A2, which is in the same format as Table 3. For both men and women, there is no discontinuity in cohort size, regardless of optimal bandwidth choice and polynomial order of the running variable.

post-Cultural Revolution cohorts to enroll in university. This is not factually correct, as there were age restrictions on who could enter college after the Cultural Revolution. These age restrictions barred the Cultural Revolution cohorts from entering college for several years, which means they did not compete with several cohorts who came after the Cultural Revolution for university positions. In other words, at the threshold, there is no spillover effect from pre- to post-Cultural Revolution cohorts.

Another explanation for the small effect of the Cultural Revolution on educational attainment is that the supply of higher education increased in later years, particularly during the 1990s after the war. In fact, the Cultural Revolution reduced the supply of higher education in the years that followed it; according to statistics from the Ministry of Higher Education, almost 8,000 professors or close to half of the total university faculty members in Iran were purged (Ashraf 1997). This purge significantly reduced the capacity when universities re-opened. To compensate, many remaining professors were asked to teach at more than one university, and some even flew on a regular basis to other cities to teach additional courses.[21] Although there had been attempts to rejuvenate the supply of higher education by establishing a teacher/professor training college in Tehran and founding a private university with campuses across the country in small towns, it took years for the higher education system to reach the pre-Cultural Revolution supply levels.

A similar argument for the small discontinuity in the educational attainment rate is that the affected cohorts went to war, but when they came back, their veteran status gave them a preferential treatment in entering college. They received a special quota that gave them a higher chance to enter college than the regular college applicants. But there are several reasons to argue that without a large

---

[21] This had a toll on research productivity of the faculty as well. Khosrokhavar et al. (2014) report that the number of respectable journal publications decreased from 450 in 1979 (prior to Cultural Revolution) to at most 120 in 1985 (three years after universities re-opened).

demand for higher education, these preferential treatments alone could not have changed the outcome by much. First, in both developed and developing countries, people rarely return to school once they dropped out of the education system, which is part of why keeping children in the educational system (rather than enticing adults to go to school) is a top priority for education policymakers. The fact that these cohorts returned to school despite being away from it for several years shows their large demand for education. Second, the national examination to enter college has been an extremely difficult one. At the time, only the top 20-30% of the exam takers were able to enter college. The stakes of the exam is high as it defines almost everything about one's future life and career. Parents invest for years in their children to make sure they rank high enough in this examination. It is common that a student spends 16 hours a day for several months to prepare for this exam. The affected cohorts who had been away from school for several years and most likely forgot all they learned there, had to compete with younger cohorts, who were fresh out of high school, in this tough examination. They had less advantage in that regards compared to the younger cohorts. Third, the experiences of the Iran-Iraq war left physical and mental scars on the affected cohorts, from post-traumatic stress disorder (PTSD) to losing limbs. This could have reduced their ability to compete in this tough examination. Therefore, the fact that these cohorts pursued education despite these barriers suggests a strong demand for higher education.

The effect on women's educational attainment is practically zero, though the situation is slightly different for women than for men. The results for women are presumably the pure effect of the Cultural Revolution, as they were excluded from serving in the war. In addition, only 5% of women in cohorts close to the Cultural Revolution period enrolled in college. In other words, this small fraction of women who enrolled during that period likely were quite different from the rest and had such a strong demand for university education that they would have enrolled as soon as the opportunity presented itself. Moreover, in Iran, the common perception is that a woman can only

gain status in society and within her family through education. This may suggest there are stronger incentives for women than for men to pursue higher education. In fact, since the 2000s, over 60% of college enrollees in Iran have been women. This strong demand for education suggests the effect of university closure on women's educational attainment would be smaller than on men's attainment.

Using the 2% sample of the 1996 census,[22] one can see that by 1996, almost 11% of men and 5% of women in the 1964 cohort, the last to face closed doors, had attended college (Figure 4). The rate for women is identical to the rate found in the 2006 and 2011 censuses for the same cohort (Figure 1). For men, the rate is close to the 13% depicted for the same cohort in Figure 1 (2006 and 2011 censuses). Therefore, one can conclude that most of the increase in college-attainment rate for the affected cohorts occurred in just 14 years following the Cultural Revolution, which is another indicator of the high demand for college education.

4.4 Returns to College Education

A natural next step is to see if this exogenous decline in men's educational attainment due to the Cultural Revolution had any impact on wages. Unfortunately, wage rates (or income levels) are not reported in the census data, but job categories are. HIES data, however, include both income and hours worked since 2006, which can be used to estimate hourly wages for salaried workers. In this section, we estimate the impact of the Cultural Revolution and its exogenous increase in education on job status using census data, and subsequently the returns on wages using the HIES data.

---

[22] This census is not publicly available. To make sure the results are replicable, I refrained from using this census in the rest of the paper. The 2% sample of the 1996 census has over 1.7 million observations. I do not have access to the 1986 census.

The census data does not include a variable to indicate job status, but occupation is reported following the International Standard Classification of Occupations (ISCO) in ten categories: 1) Legislators, senior officials and managers, 2) Professionals (doctors, lawyers, engineers, etc.), 3) Technicians and associate professionals, 4) Clerks, 5) Service workers and shop and market salespeople, 6) Skilled agricultural and fishery worker, 7) Crafts and related trades workers, 8) Plant and machine operators and assembly workers, 9) Elementary occupations, and 10) Armed forces. Excluding the armed forces, these job categories arranged hierarchically, with legislators, senior officials, and managers in the top category and the elementary occupations in the bottom. I exclude "armed forces" from this calculation, as it is not an informative job category. Because there is significant heterogeneity in the jobs in the armed forces, and job status depends on the individual's military rank, which is not reported in the data.[23]

I use the log of average wage for each job category as a measure of status for that job category.[24] These average wages are both a cardinal and an ordinal measure, as well as a measure of economic returns. Census data, however, reports neither income nor hours worked. Therefore, HIES data

---

[23] Additionally, including "armed forces" in the estimations does not affect the results (compare Table OB13 in the Online Appendix with Table 4).

[24] As previously mentioned, job categories seem to be arranged hierarchically. Based on this hierarchy, one can convert this categorical variable into an ordinal variable for job status. Converting job categories into a quantitative measure of job status, however, is somewhat challenging. For example, how does one quantify the difference in job status between categories, e.g., between Technicians and associate professionals (category 3), and Clerks (category 4)? One subjective solution is to aggregate job categories of perceived comparable status into one group and separate those that differ significantly into other groups. For example, categories 8 and 9 can be combined into one group, and the lowest value of job status, 1, is assigned to them. Categories 5, 6, and 7 are aggregated into another group with value 2 assigned to their job status); categories 3 and 4 into a third group with a value of 3 for job status, and categories 1 and 2 into a fourth group with value 4 assigned to their job status. Although the results based on this definition of job status are reported in Table OB10 in the Online Appendix, there are at least two issues with this (or any) subjective definition of job status: first, how one decides which categories should be combined, and second, what values one assigns to each of these categories. The values assigned above assume that for example, categories 1 and 2 are four times better than categories 8 and 9 and two times better than categories 5, 6, and 7. Using average wage mitigates both of these issues.

from 2006 through 2015 are used to calculate average wages (adjusting for inflation). The results are shown in Table A3 (Appendix) and demonstrate a clear hierarchy among these job categories.[25]

Once the job status variable was defined as noted above, two methods were employed to estimate the impact of the Cultural Revolution. First, job status is defined as the dependent variable in Equation (1), which allows the discontinuity in job status (log of average wage of a job category) due to the Cultural Revolution to be estimated, i.e., the reduced form. The discontinuity is reported in Panel A of Table 4. Columns (1) and (2) are first- and second-degree polynomial RDD estimates using birth year data, and Columns (3) and (4) are based on birth month data. All estimates are statistically significant, and three of them show a 2.2% to 2.4% reduction in the average wages of the job category one holds (job status) due to the Cultural Revolution. The lowest estimate is -1.2%. In Panel B, 2SLS is employed to estimate the causal impact of college attendance on job status, using Cultural Revolution as an instrument for college attendance. The first stage is the RDD reported in Tables 2 and 3. The discontinuity is the exogenous variable (instrument). Similar to Panel A, the first two columns use the first- and second-degree polynomial RDD, using birth year data in the first stage; and the last two columns are based on birth month data. The birth year results show that those who attended college had a 66% to 88% increase in their job category average wages (job status). The estimates in the last two columns, which have birth month RDD in the first stage, show a return of about 100%. The estimate in the last column, which uses a second-degree polynomial RDD in the first stage on birth month data, is not reliable, as the instrument in its first stage is a weak predictor of college attendance. The Kleibergen-Paap rk Wald F statistic, which tests the weakness of the instrument, is reported under each estimate. Stock and Yogo (2005) calculate the critical value for this statistic as 16.38. In all 2SLS regressions, except the one in the last column, we

---

[25] Moreover, a closer look at the results reveals that the subjective definition of job status, based on the nine job categories, described earlier is not unreasonable.

reject the null hypothesis that the instrument is weak. Overall, the results show that those who attended college gain about 66% to 100% in their job category average wages over those without college education. Note that the average person close to the threshold who did not go to college has middle school education.[26]

A more interesting result is one that uses individual level wages rather than job status. As previously mentioned, the census data do not contain information on wages; thus, wages are calculated using HIES annual surveys. A sample of over 100,000 salaried workers whose birth year is ±15 years around the threshold is obtained by combining the HIES data from 2006 through 2015. Using these data and the same methods as in Table 4, the impact of the Cultural Revolution on individuals' wages is estimated. As mentioned in Section 3, however, only birth year can be used to identify discontinuities, as the HIES dataset does not contain birth month. The results are shown in Table 5, which is organized in a similar fashion to Table 4. Panel A reports the discontinuity in the log of wages for men due to the Cultural Revolution, which was calculated using the same first- and second-degree polynomial RDDs as in Equation (1). They show that the Cultural Revolution reduced wages of individuals within the affected cohorts by about 5% (4.7% to 5.5%). Panel B reports both the OLS regression and the 2SLS estimates of the return to college education and above. As in Table 4, the 2SLS estimates use the discontinuity due to the Cultural Revolution as an instrument for college attainment. Age and age squared are controlled for by following a simple Mincer equation. The OLS estimate shows an almost 76% return to college education and above, but the 2SLS estimate is larger, at about 100% (Column (2) in Panel B). This 2SLS estimate is interestingly close to the numbers found for job status in Table 4, although they use completely different datasets and methodologies. These results show that those with college education and

---

[26] The distribution of education around the threshold in the census data is reported in Table OB11 in the Online Appendix.

above have wages twice as high as those with less than college education. The average person close to the threshold who did not go to college in these data has middle school education.[27] Note that the result in Column (3) of Panel B is unreliable, as the first stage regression is weak. Overall, these high returns to college education could explain the strong demand for college among the Cultural Revolution cohorts.[28]

Despite the fact that returns to education are the subject of heated discussions in policy and academic circles, there are no studies that estimate these returns free of bias in the Middle East and North Africa (MENA) region, except for Turkey. There are, however, dozens of studies that use the Mincer equation[29] to estimate returns in various countries in the region, many of which have remained unpublished. A recent study, Rizk (2016), finds the returns to the tertiary level to be 61% in Egypt, 64% in Palestine, 74.5% in Tunisia, and 76.7% in Sudan. The OLS estimate reported in Table 5 of this study is comparable to these estimates. But this study shows that the true estimate is larger at about 100%. They are also robust to using two different datasets and two different methodologies (Tables 4 and 5). The MENA region is the only region in the world in which unemployment is higher for college educated than for less-than-college educated. Hence, some have argued that returns to college education are low and some college graduates are over-educated. This study finds that contrary to public perception, return to college education is substantially high, even higher than estimated in the past. In addition, it does not find that college education results in higher

---

[27] The distribution of education around the threshold in the HIES data is reported in Table OB12 in the Online Appendix.

[28] One can split the sample into rural and urban areas and estimate the same RDD and 2SLS procedures on these subsamples. The results show that the discontinuity in individuals' wages is statistically significant in both areas but seems to be larger in urban areas. The 2SLS estimates, however, are only reliable in urban areas, as the first stage is weak in rural areas. The return to college education and above in urban areas is estimated at 88%. These results are reported in Tables OB14 and OB15 in the Online Appendix. One should note that these results are subject to selection, as there has been substantial migration from rural to urban areas over time. Therefore, I refrain from including them as part of the paper.

[29] And sometimes with wrong specifications.

unemployment rates or lower labor force participation (LFP). Similar to job status, one can estimate the Cultural Revolution impact on these two labor market outcomes. Tables OB16 and OB17, which follow the same structure as Table 4, report such estimates and show that there is little evidence for any causal impact of college education on unemployment or LFP. The estimates are insignificant or change sign based on the specification. Therefore, although unemployment rate can be higher among the college-educated youth, it does not seem to be different for the college-educated in cohorts close to the Cultural Revolution.

5. Conclusion

The contemporary history of Iran is fascinating and puzzling. In the span of a few months, the monarchy collapsed, and new institutions emerged to dominate the political landscape. Almost overnight, the ruling class was replaced with a new elite that had not held similar political power in the past. For the first few years following the revolution, Iran was in turmoil and had to deal with civil war, emigration and diaspora of the old elite and educated classes, as well as the Iraqi invasion and ensuring Iran-Iraq war.

In the midst of these crises and to secure its control and authority over them, the new Iranian government closed all universities for 30 months. Cohorts who would normally have matriculated to college, but were unable to do so due to university closures, were instead drafted into the Iranian armed forces and fought in the Iran-Iraq war. In this study, I showed that cohorts affected by the closure of universities and the draft were almost as likely to have been college educated as cohorts after the universities re-opened. This is evidence of a strong demand for education (among these cohorts) in Iran. This strong demand is also evident in the rapid rise in average years of education during and after the Iran-Iraq war and afterwards. Human capital investment was a cornerstone of

the Iranian household after World War II, and it has remained a resilient feature of household economics in Iran.

Further anthropological and sociological research is necessary to understand how these affected cohorts gained the education they wanted years after they left high school.

(b) quadratic - men
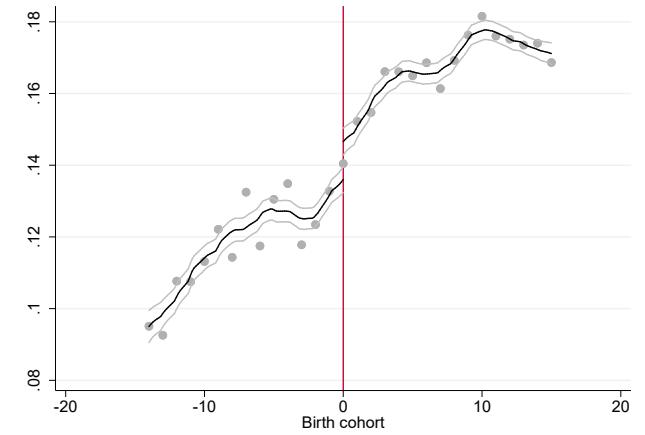

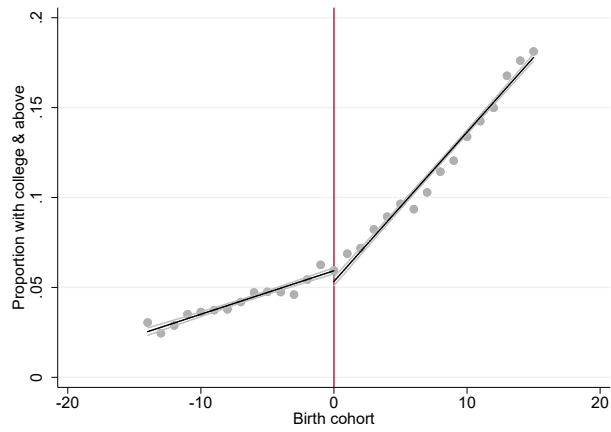

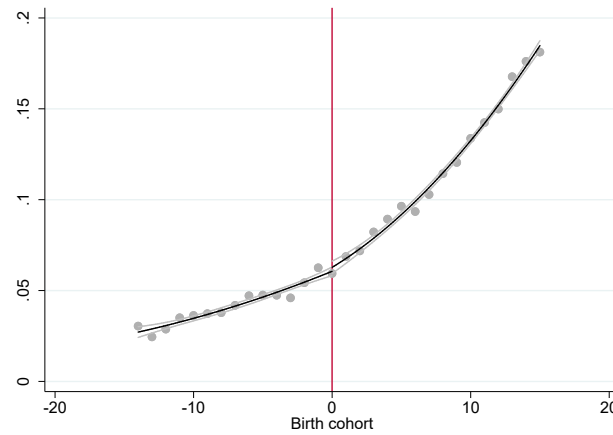

(c) local polynomial smooth line - men

(d) linear - women
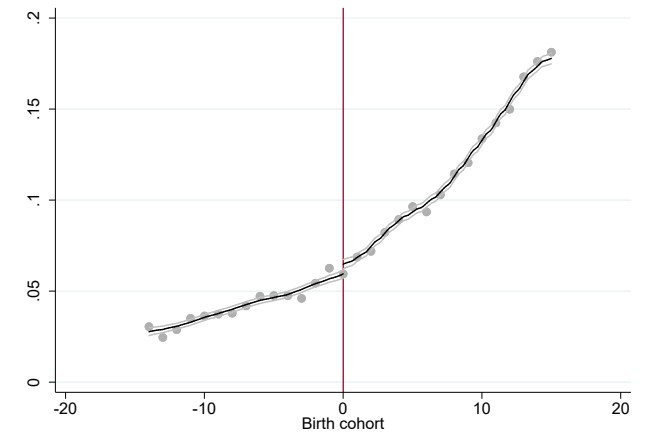

(e) quadratic - women

(f) local polynomial smooth line - women

Note: The dots represent the proportion in each birth year cohort who partially or fully completed an undergraduate or graduate degree. The curves depict linear, quadratic, and local polynomial predictions respectively.

Figure 3 – Discontinuity in the proportion of men and women with college education and above (vertical axis) across monthly birth cohorts (horizontal axis)
(1931 through 1984 birth cohorts)
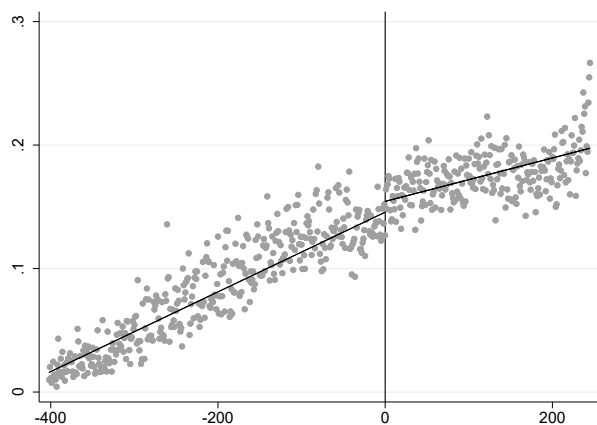

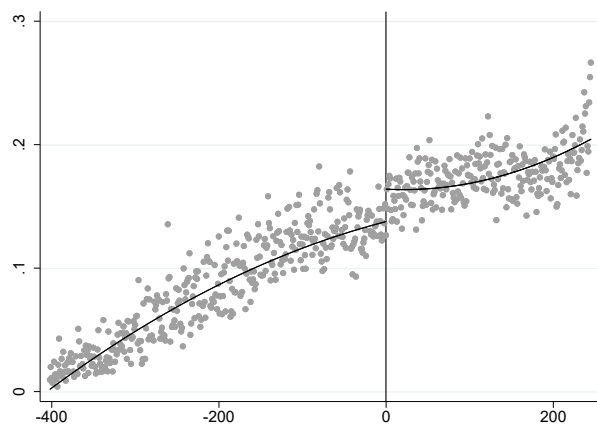

(a) local linear - men   (b) local quadratic - men   (c) local polynomial of the 3rd order - men
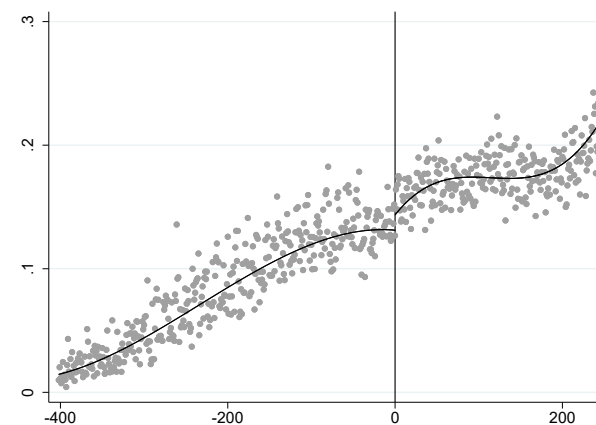

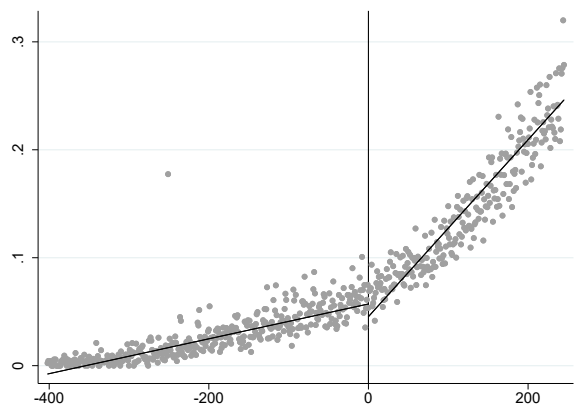

(d) local linear - women   (e) local quadratic - women   (f) local polynomial of the 3rd order - women
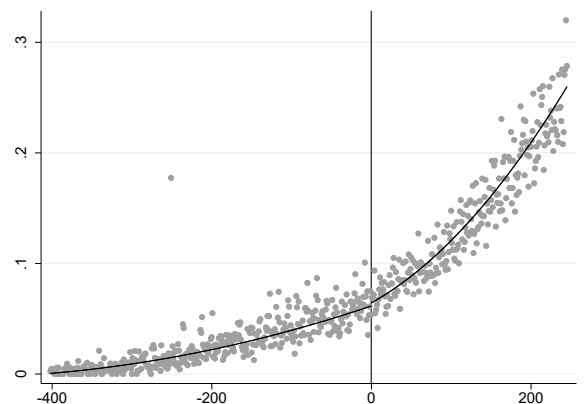

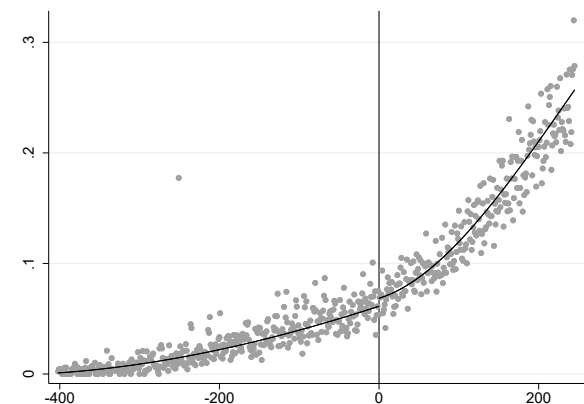

Note: The vertical axis represents the proportion of the birth cohort who partially or fully completed an undergraduate or graduate level education. The figures are drawn with `rdplot` command in Stata to find the optimal bin size. The dots represent the proportion in the bin who partially or fully completed an undergraduate or graduate degree. The curves represent first, second, and third order local polynomial predictions.

34

Figure 4 – Proportion of men and women with college education and above in the 1996 Census
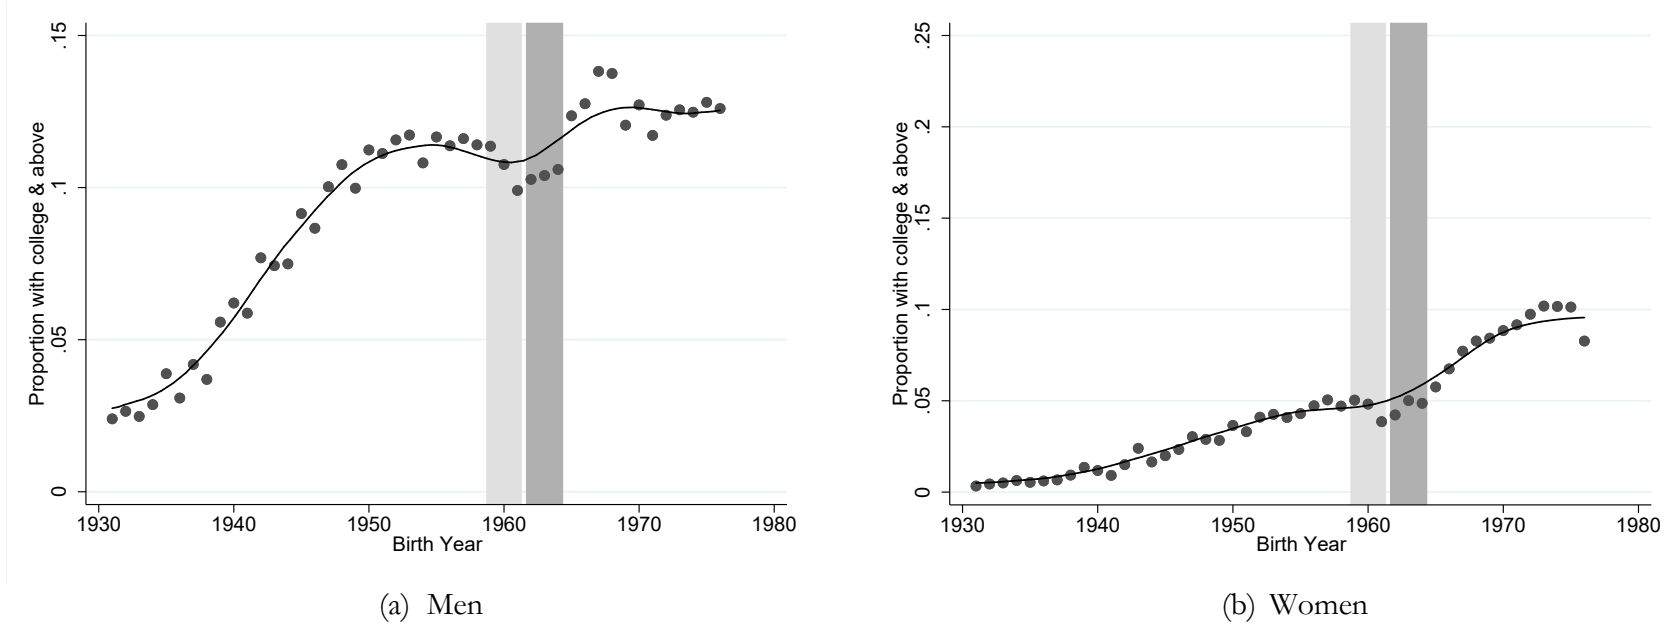

(a) Men

(b) Women

Note: College and above represents attainment of partial or complete undergraduate or graduate level education. Birth cohorts of 1962, 1963, and 1964 are shaded with dark gray as they reached age 18 when universities were closed. Birth cohorts of 1959, 1960, and 1961 were in school just before the universities were closed. So their education could have remained incomplete. They are shaded with light gray.

Tables

Table 1 – Summary Statistics

Variable	Observations	Mean	St. dev.	Min	Max
Panel A – 2006 and 2011 Censuses					
Female	1,419,591	0.50	0.50	0	1
Age	1,419,591	41.31	13.77	22	80
Literate	1,419,591	0.77	0.42	0	1
Primary school	1,419,591	0.25	0.43	0	1
Middle school	1,419,591	0.15	0.36	0	1
High school	1,419,591	0.19	0.39	0	1
College & above	1,419,591	0.13	0.34	0	1
Birth year	1,419,591	1967.03	13.59	1931	1984
Birth month	1,372,865	6.20	3.09	1	12
Panel B – Household Income and Expenditure Surveys, 2006-2015 (Male Wage Earners in 1950 to 1979 Birth Cohorts)					
ln(wage)	107,814	11.47	0.62	7.20	16.45
Age	107,814	41.79	7.75	27	65
Urban	107,814	0.55	0.50	0	1
College & above	107,814	0.12	0.33	0	1

Note: Female is a dummy equal to one if the individual is a female and zero otherwise. College & above is a dummy variable equal to one if the individual has attended college or graduate school. Note that Birth years are reported in Gregorian calendar, but they are in Solar Hijri (Persian) calendar in the dataset. The sample for censuses includes individuals whose birth year is between 1931 and 1984. The sample for Household Income and Expenditure Surveys includes only male wage earners in cohorts of 1950 through 1979. ln(wage) is the natural log of gross wages for wage earners. Gross annual salary is divided by the hours worked per week.

Polynomial order of RD in the 1st stage	1st	2nd	1st	2nd
Observations	370,805	370,805	495,928	495,928

Note: The table consists of two panels and four columns. The first two columns in both panels use the birth year analysis, and the last two columns are based on birth month analysis. For birth year data, the bandwidth is chosen as ±15 years, i.e., those born between 1950 and 1979. For birth month data optimal bandwidth and bin size are selected using Coverage Error Rate-Two sided procedure. The top panel reports the discontinuity in men's job status, measured as the average wage in a job category. The bottom panel reports the second stage of a 2SLS that uses discontinuity in Cultural Revolution in an RD as instrument for college & above education to estimate the impact of college education on job status. In the analysis using the birth year data (Columns (1) and (2)) and following a suggestion by Lee and Lemieux (2010), robust-heteroskedastic standard errors corrected for correlation within each birth year cohort (the running variable) are estimated and reported in parentheses, because the running variable is discrete. For birth month data (Columns (3) and (4)), Bias-Corrected RD estimates are reported in this table.
 *** p<0.01, ** p<0.05, * p<0.10
† Bandwidth is ±15 years, i.e., those born between 1950 and 1979.
‡ Optimal bandwidth choice method is Coverage Error Rate – Two Sided (two different optimal bandwidth choices above and below the threshold). Bias-Corrected coefficients and standard errors are reported.
[Π] This is the Kleibergen-Paap rk Wald F statistic for weak instruments. The 10% critical value of this statistic, calculated by Stock and Yogo (2005), is 16.38.

Data Source: Household Income and Expenditure Surveys, 2006-2015; Author's Calculations.

Online Appendix A

We need a more careful consideration of data than a visual observation to see if there has been a statistically significant difference in the educational attainment of the affected and partially affected cohorts relative to others. One way to do this is to look at the deviation from the trend for these cohorts. In other words, one may run the following regression:

$$C_{is} = \alpha_s + \beta_1 T1_{is} + \beta_2 T2_{is} + f(B_{is}) + u_{is} \tag{A1}$$

in which C_{is} is a dummy equal to one, if individual i in region s has partially or fully attended undergraduate or graduate schools. The symbol α_s denotes region fixed effects. There are two regions per province: one representing all urban areas in a province and another for all rural areas in that province. Because there were 30 provinces in 2006, the total number of clusters is 60.[1] All results have robust-heteroskedastic standard errors corrected for within region correlations. The symbol $T1_{is}$ is a dummy variable equal to one if individual i in region s belongs to birth cohorts that were fully affected (i.e., 1962 through 1964) and zero otherwise. Similarly, $T2_{is}$ is a dummy variable equal to one if individual i in region s belongs to birth cohorts that were partially affected (i.e., 1959 through 1961) and zero otherwise. The symbol B_{is} is the year individual i in region s was born (i.e., it is the birth cohort). The symbol $f(B_{is})$ is a function that picks up a linear or non-linear trend. Based on the shape of the graphs in Figures 1(a) and 1(b), we use the following: 1) a linear trend (only B_{is}), 2) quadratic trends (B_{is} and B_{is} squared), and 3) differential linear trends before and after the Cultural Revolution. Both β_1 and β_2 show deviations from the trend for cohorts who were fully or partially affected by the Cultural Revolution. Table B1 reports the results.

---

[1] There were 31 provinces in 2011. The provinces in 2011 were matched with those in 2006 to create consistent regional data over time.

Column (1) in Table B1 depicts the regression in Equation (A1) using the sample of males in the birth

cohorts of 1931 through 1984 and a linear trend. The coefficient of T1 shows that cohorts of men who

were fully affected by the Cultural Revolution had about a 1.2 percentage-point lower rate of college (and

above) attainment than the trend. The coefficient of T2 depicts that for those who were partially affected,

the attainment rate was the same as the linear trend.

Considering a linear trend for college attainment rate may be strong (see Figures 1(a) and 1(b)).

Alternatively, one may consider a quadratic trend. But as Column (2) of Table B1 shows, adding the trend

squared, i.e., B_{is}^2, has little impact on the results for the sample of men.

One may argue that after the Cultural Revolution, the transformation of institutions of higher education

might have affected the trend altogether. This is easy to control by adding AR_{is} and its interaction with the

trend variable, B_{is}, to Equation (A1). The symbol AR_{is} is a dummy equal to one if individual i in region s

was born after 1961 and zero otherwise. The interaction of this variable and the trend picks up the change

in trend after the Cultural Revolution. The results for men are reported in Column (3). The coefficient of T1

shows a -1.5 percentage-point deviation from the trend before the Cultural Revolution. But the deviation

for the partially affected cohorts remains insignificant and small.

Column (4) represents the same regression as Column (1) but for women. The coefficients of T1 and T2

imply that attainment rates for cohorts fully or partially affected by the Cultural Revolution were four

percentage points below the trend. However, as shown in Figure 1(b), the trend for women is more like a

quadratic one. Hence, birth year squared should be added to the specification. Column (5) reports the

results for such a specification. The deviations found in Column (4) become significantly smaller from about

four percentage points to less than one.

Another specification is to control for separate trends before and after the Cultural Revolution. Column (6)

depicts the results. The coefficients imply that attainment rate for female cohorts who were fully affected by

the Cultural Revolution was 2.2 percentage points *larger* than the trend. This is an odd result and clearly

shows that the deviations from the trend for women are sensitive to the specification.

Observations	370,805	370,805	495,928	495,928

Panel B – 2SLS Estimate of the Impact of College Attendance on Job Status
(using Discontinuity in College Attendance, due to Cultural Rev., as IV)

College Attendance	1.566***	1.803***	1.958***	2.386***
	(0.125)	(0.431)	(0.441)	(0.726)
Kleibergen-Paap rk Wald F Statistic[Π]	223.7	18.50	18.05	7.602
Polynomial degree	1st	2nd	1st	2nd
Observations	370,805	370,805	495,928	495,928

Note: See notes in Table 4. The only difference between this table and Table 4 is that the job status variable is a categorical variable defined as follows: plant and machinery workers and elementary occupations are combined into one group, and the lowest value of job status 1 is assigned to them. Service workers, salespeople, skilled agricultural workers, and crafts and trades workers are aggregated into another group, and value 2 is assigned to their job status. Technicians and clerks are combined into a third group with the value of 3 for job status, and government and private sector managers, and doctors, lawyers, engineers and other professionals are aggregated into a fourth group and value 4 is assigned to their job status.
 *** $p<0.01$, ** $p<0.05$, * $p<0.10$
† Bandwidth is ±15 years for those born between 1950 and 1979.
‡ Optimal bandwidth choice method is Coverage Error Rate – Two Sided (two different optimal bandwidth choices above and below the threshold).
[Π] This is the Kleibergen-Paap rk Wald F statistic for weak instruments. The 10% critical value of this statistic calculated by Stock and Yogo (2005) is 16.38.

Polynomial order of RD in the 1st stage	1st	2nd	1st	2nd
Observations	469,544	469,544	495,928	495,928

Note: The table consists of two panels and four columns. The first two columns in both panels use the birth year analysis and the last two columns are based on birth month analysis. For birth year data, the bandwidth is chosen as ±15 years, i.e., those born between 1950 and 1979. For birth month data, optimal bandwidth and bin size are selected using Coverage Error Rate-Two sided procedure. The top panel reports the discontinuity in men's job status (measured as the average wage in a job category). The bottom panel reports the second stage of a 2SLS that uses discontinuity in Cultural Revolution in an RD as instrument for college & above education to estimate the impact of college education on job status. In the analysis using the birth year data (Columns (1) and (2)) and following a suggestion by Lee and Lemieux (2010), robust heteroskedastic standard errors corrected for correlation within each birth year cohort (the running variable) are estimated and reported in parentheses, because the running variable is discrete. For birth month data (Columns (3) and (4)), Bias-Corrected RD estimates are reported in this table.
 *** $p<0.01$, ** $p<0.05$, * $p<0.10$

The bottom panel reports the second stage of a 2SLS that uses discontinuity in Cultural Revolution in an RD as instrument for college & above education to estimate the impact of college education on job status. In the analysis using the birth year data (Columns (1) and (2)) and following a suggestion by Lee and Lemieux (2010), robust heteroskedastic standard errors corrected for correlation within each birth year cohort (the running variable) are estimated and reported in parentheses, because the running variable is discrete. For birth month data (Columns (3) and (4)), Bias-Corrected RD estimates are reported in this table.
 *** $p<0.01$, ** $p<0.05$, * $p<0.10$
† Bandwidth is ±15 years, i.e., those born between 1950 and 1979.
‡ Optimal bandwidth choice method is Coverage Error Rate – Two Sided (two different optimal bandwidth choices above and below the threshold). Bias-Corrected coefficients and standard errors are reported.
Π This is the Kleibergen-Paap rk Wald F statistic for weak instruments. The 10% critical value of this statistic, calculated by Stock and Yogo (2005), is 16.38.
